Summary

The knowledge about tendons and tenocyte biological behaviour during aging and, especially, oestrogen deficiency is limited. Women differ from men with regard to muscle and tendon, most likely due to differences in sex hormones activity and tissue response. To-date the interest in metabolic factors that may induce tendon disorders is growing. The aim of this paper is to elucidate the current findings in the correlation between oestrogen deficiency, aging and tendon pathology and to encourage future researches to ameliorate assessment and management of tendinopathies in postmenopausal women.

KEY WORDS: tendinopathies, metabolic disease, oestrogens hormones.

Introduction

During aging occur paraphysiological changes in the musculoskeletal system such as decrease in muscle mass and strength, alteration of tendon and bone structure. It was observed that these alterations are due to a decrease in collagen synthesis, increase in free radicals expression and metabolism imbalance in favor of catabolic activity. It was suggested that in females the level of estrogen, which decreases drastically in the post-menopause period, plays a crucial role influencing tendon metabolism and altering the production of different growth factors. Menopause consist in a rapid oestrogen decrease in the first 6 months, that continues for about 3 years. At the same time is observed the peak concentration of gonadotrophins. For the rest of woman life the level of estradiol and estrone remains constantly very low, without the typical periodic fluctuation that characterize fertile period. Before menopause the risk of developing tendon pathology in women is lower than in men, whereas in older women the incidence of tendinopathy and tendon rupture is similar to coetaneous men. It is also been shown that dynamic adaptation to mechanic loading may be different between women and men.

In a recent study conducted by Abate et al. it was observed that in postmenopausal women there is a dramatic increase in asymptomatic rotator cuff tears and that this higher prevalence was linked also to other metabolic factors like HDL, fasting glucose and Body Mass Index (BMI).

Materials and methods

We performed a comprehensive search of PubMed, Medline, Cochrane, CINAHL, Embase, Sport Discus, Pedro and Google scholar databases using various combinations of the keywords ‘postmenopausal women’, ‘tendinopathy’, ‘tendon’, ‘oestrogen deficiency’, ‘aging’. Selected literature was limited to original articles and to English, Italian and Spanish languages. This article submits to the ethical standards of the journal.

Aging and tendon: preclinical and clinical findings

Tendons primarily consist of collagen, arranged in linear fibrils, in which tenocytes are the main cellular component. Tenocytes produce collagen, repair proteins, and matrix proteoglycans. Thus, the function, mechanics and homeostasis of tendon tissue depend on the activity of tenocyte, which is essential to maintain tendon characteristics by the capacity of remodel extracellular matrix (ECM). Age-related changes in tenocyte behavior are responsible for altered migration and proliferation rate, leading to ineffective repair processes and increase in frequency of tendon injuries.

Tsai et al. in an in vitro experiment performed on tenocytes derived from young, middle-age and old Sprague-Dawley rats, showed that decline in proliferation is di-
directly correlated to aging and that aged tenocytes tend to stop in G0/G1 cellular phase. Furthermore, in tenocytes from old rats, it was observed down-regulation in cellular senescence-inhibited gene (CSIG), up-regulation in p27 (a CDK inhibitor that arrest cell cycle) and over-expression of senescence-associated b-galactosidase (SA b-gal) has been proposed to be a universal marker of aging. Torricelli et al. confirmed the reduction in tenocyte proliferation rate, in an in vitro study on tenocytes derived from Achilles tendon of rats. Furthermore, it was observed age-related lower production of collagen I, aggrecan and elastin. The decrease in collagen I production is in accordance with other studies performed in vitro and in vivo. Recently stem cells, which are called tendon-derived mesenchymal stem cells (TD-MSCs), have been identified both in human and animal tendons. Beside tenocytes, stem cell population may be involved in tendon homeostasis and repair, by replacing mature cells lost, or in the pathogenesis of tendinopathy. Ruzzini et al. found that the number of tendon stem cells and self renewal potential are reduced in old patients compared to young patients, leading a possible role of impaired stem cell potential and variation in tendon structure during aging.

Although different studies in various animal models report alterations in tendon stiffness, fibril structure and collagen content during aging, the findings of modifications in tendon mechanical properties are contradictory. Wood et al. found age-related increase in tangent modulus in old rats tibialis anterior tendon, but no differences in cross sectional area (CSA) or in fibril diameter and morphology. Similar results were obtained in tibialis anterior and flexor digitorumlongus muscle tendons with a significant increase of the elastic stiffness with aging in rats. On the other hand there are also evidence to the opposite, with decrease or constant stiffness related to age. Equally, also human trials performed are inconsistent, which may partly be related to methodological study design and physical activity level differences of the samples. Indeed, some author shave shown alteration in mechanical properties while others have not shown any significant variation between young and old patients. Furthermore, tendon stiffness during aging may be influenced by the accumulation of Advanced Glycation End-Products (AGEs). AGE formation is high in tendon tissue because the turnover of mature collagen is slow, leaving enough space for further cross-linking through non-enzymatic reactions. Couppe et al. found that both enzymatic cross-links and pentosidose, which is a marker of AGE, where more abundant in the patellar tendon of old men compared with that of young men and they supposed that higher non-enzymatic cross-link density in elderly served to maintain tendon stiffness despite the diminished collagen concentration. Li et al. observed that AGE accumulation may significantly reduce collagen fiber sliding without tendon structure stiffening even if it was reveal a compensatory collagen fiber stretch.

Recently, the contribution of non-collagenous proteins of extra-cellular matrix has been closely studied, considering that age related alterations in proteoglycans (PGs) may affect the structure and mechanical properties of tendon. To-date class I small leucine-rich proteoglycans (SLRPs), biglycan and decorin have been identified as important regulators of tendon development, aging and healing.

**Oestrogen deficiency and tendon: preclinical and clinical findings**

The presence of oestrogen receptors (ER) in tenocytes is been demonstrated in human and animal trials. These findings may indicate that tenocytes are influenced by oestrogen level. Bridgeman et al. observed both ERα and ERβ in normal and disease tendon of male and female patients, without any statistically significant difference. On the other hand the impact of ovariectomy (OVH) on gene expression in rabbit resulted different in various tendons that may indicate variances in number and distribution of oestrogen receptors. Oestrogen level has a direct effect on collagenous tissue in several preclinical studies. The reduction of blood oestrogen level is associated with reduction in tensile strength, decrease in collagen synthesis, fibre diameter, density and increase degradation in tendon tissue. Cicci et al. found a correlation between oestrogen deficiency, down-regulation of collagen turnover and alteration in collagen fibre orientation. Furthermore the group composed by sham-operated rats exhibits a greater tenocyte proliferation rate and inflammatory response after an Achilles tendon injury compared with ovariectomised oestrogen-deficient rats, meaning a potential role of endogenous oestrogens in improving tendon healing. This could be explained by a direct effect of oestrogen deficiency on tenocytes. Indeed, in a micro-wound in vitro model, tenocytes derived from ovariectomised rats show less tenocyte viability, cell migration speed and a poor quality of healed tissue in comparison not only to tenocytes derived from healthy young rats but also to tenocytes derived from old rats. The reduction in tensile strength and alteration in biomechanical properties are linked not only to the role of collagen but also to changes in gene expression of other important extracellular matrix (ECM) molecules like proteoglycans, inflammatory mediators and growth factors. Recently it was observed a 10-fold lower expression of aggrecan and decrease in other PGs (biglycan, decorin, versican) in OVH rabbits, moreover it was also measured decrease in tissue inhibitor of metalloprotease (TIMP-2) and TGF-beta production that is correlated to imbalanced tendon metabolism.

In rabbits tendons the impact of OVH was different for Achilles tendon comparing to patellar tendon when evaluated using mRNA levels for genes including collagen, proteoglycans, proteinases and inflammatory mediators. This results may indicate that different ten-
dons have different response to oestrogens and a tendon-specific action of sex hormones. Most of studies performed on tendon and oestrogen deficiency are clinical and are founded on the administration of oestrogen replacement therapy in postmenopausal women. However currently are been performed trials exclusively in Achilles and patellar tendons. Hormone Replacement Therapy (HRT) with exogenous oestrogen may ameliorate tendon structure by preserving collagen fibre diameter. Furthermore oestrogen positively influences tendon morphology and biomechanical properties in postmenopause. In contrast with these findings, the effects of steroids hormones on tendons seems to be different in young women. Indeed, while in younger women estrogens stimulation seems to have negative effects on tendons, in older post-menopausal women they seems to have stimulating effects. In fact, in a study performed in young women, oral contraceptive users group was found to have lower collagen synthesis rate, compared to coetaneous control women. Conflicting results were obtained combining HRT and exercise therapy. In rats exercise therapy increases mature collagen replacement and fibril diameter and density, while detraining is associated with disorganization in collagen fibre arrangement. Cook et al. and Finni et al. reveal positive effect on Achilles tendon morphology in active postmenopausal women receiving HRT. On the other hand Hansen et al. found a negative correlation between tendon strength and HRT use following one-legged resistance exercise related to increasing in collagen turnover with higher immature collagen cross-linking. The discrepancy could be partially explained by the observation that oral oestrogen replacement influences liver metabolism. Specifically, oral administration may reduce circulating level of Insuline-like Growth Factor I (IGF-I) and Interleukin-6 (IL-6), that are involved in collagen synthesis during physical activity. Nevertheless, these contradictory findings may be consequent to the type of therapeutic exercise ordered to patients. Indeed, in athlete tendinopathy, eccentric exercise programs are widely used in the rehabilitation of mid-portion Achilles and patellar tendon injuries with a successful outcome. In older adults it has been revealed general preservation of eccentric strength compared to concentric strength and increase muscle mass and strength in high-intensity resistance training incorporating eccentric contractions relative to traditional training strategies. Therefore, eccentric exercise may be promising also in the prevention of tendon disorders in postmenopausal women.

Future perspectives

The relationship between oestrogen deficiency and tendon disorders during aging appears clinical relevant. Thus more studies are needed to investigate the impact of menopause in different tendons, especially in upper limb and in rotator cuff tendinopathy that dramatically increase in middle-aged women. Improvements in the understanding about this argument may rebuild assessment and management in tendon pathology.
